

Modular CPR Assist Device

This application is a continuation of U.S. Application 10/162,462 filed June 3, 2002, now U.S. Patent 6,709,410, which is a continuation of U.S. Application 09/345,635 filed June 30, 5 1999, now U.S. Patent 6,398,745, which is a continuation of U.S. Application 09/087,299 filed May 29, 1998, now U.S. Patent 6,066,106.

Field of the Inventions

This invention relates to the resuscitation of cardiac 10 arrest patients.

Background of the Inventions

Cardiopulmonary resuscitation (CPR) is a well known and valuable method of first aid. CPR is used to resuscitate people who have suffered from cardiac arrest after heart attack, 15 electric shock, chest injury and many other causes. During cardiac arrest, the heart stops pumping blood, and a person suffering cardiac arrest will soon suffer brain damage from lack of blood supply to the brain. Thus, CPR requires repetitive chest compression to squeeze the heart and the thoracic cavity 20 to pump blood through the body. Very often, the patient is not breathing, and mouth to mouth artificial respiration or a bag valve mask is used to supply air to the lungs while the chest compression pumps blood through the body.

It has been widely noted that CPR and chest compression can 25 save cardiac arrest patients, especially when applied immediately after cardiac arrest. Chest compression requires that the person providing chest compression repetitively push

down on the sternum of the patient at 80-100 compressions per minute. CPR and closed chest compression can be used anywhere, wherever the cardiac arrest patient is stricken. In the field, away from the hospital, it may be accomplished by ill-trained 5 by-standers or highly trained paramedics and ambulance personnel.

When a first aid provider performs chest compression well, blood flow in the body is typically about 25-30% of normal blood flow. This is enough blood flow to prevent brain damage. 10 However, when chest compression is required for long periods of time, it is difficult if not impossible to maintain adequate compression of the heart and rib cage. Even experienced paramedics cannot maintain adequate chest compression for more than a few minutes. Hightower, et al., Decay In Quality Of 15 Chest Compressions Over Time, 26 Ann. Emerg. Med. 300 (Sep. 1995). Thus, long periods of CPR, when required, are not often successful at sustaining or reviving the patient. At the same time, it appears that, if chest compression could be adequately maintained, cardiac arrest patients could be sustained for 20 extended periods of time. Occasional reports of extended CPR efforts (45-90 minutes) have been reported, with the patients eventually being saved by coronary bypass surgery. See Tovar, et al., Successful Myocardial Revascularization and Neurologic Recovery, 22 Texas Heart J. 271 (1995).

25 In efforts to provide better blood flow and increase the effectiveness of bystander resuscitation efforts, modifications of the basic CPR procedure have been proposed and used. Of primary concern in relation to the devices and methods set forth below are the various mechanical devices proposed for use in 30 main operative activity of CPR, namely repetitive compression of the thoracic cavity.

The device shown in Barkolow, Cardiopulmonary Resuscitator Massager Pad, U.S. Patent 4,570,615 (Feb. 18, 1986), the commercially available Thumper device, and other such devices, provide continuous automatic closed chest compression. Barkolow 5 and others provide a piston which is placed over the chest cavity and supported by an arrangement of beams. The piston is placed over the sternum of a patient and set to repeatedly push downward on the chest under pneumatic power. The patient must first be installed into the device, and the height and stroke 10 length of the piston must be adjusted for the patient before use, leading to delay in chest compression. Other analogous devices provide for hand operated piston action on the sternum. Everette, External Cardiac Compression Device, U.S. Patent 5,257,619 (Nov. 2, 1993), for example, provides a simple chest 15 pad mounted on a pivoting arm supported over a patient, which can be used to compress the chest by pushing down on the pivoting arm. These devices are not clinically more successful than manual chest compression. See Taylor, et al., External Cardiac Compression, A Randomized Comparison of Mechanical and 20 Manual Techniques, 240 JAMA 644 (Aug. 1978).

Other devices for mechanical compression of the chest provide a compressing piston which is secured in place over the sternum via vests or straps around the chest. Woudenberg, Cardiopulmonary Resuscitator, U.S. Patent 4,664,098 (May 12, 25 1987) shows such a device which is powered with an air cylinder. Waide, et al., External Cardiac Massage Device, U.S. Patent 5,399,148 (Mar. 21, 1995) shows another such device which is manually operated. In another variation of such devices, a vest 30 or belt designed for placement around the chest is provided with pneumatic bladders which are filled to exert compressive forces on the chest. Scarberry, Apparatus for Application of Pressure to a Human Body, U.S. Patent 5,222,478 (Jun. 29, 1993) and

Halperin, Cardiopulmonary Resuscitation and Assisted Circulation System, U.S. Patent 4,928,674 (May 29, 1990) show examples of such devices. Lach, et al., Resuscitation Method and Apparatus, U.S. Patent 4,770,164 (Sep. 13, 1988) proposed compression of 5 the chest with wide band and chocks on either side of the back, applying a side-to-side clasping action on the chest to compress the chest.

Several operating parameters must be met in a successful resuscitation device. Chest compression must be accomplished 10 vigorously if it is to be effective. Very little of the effort exerted in chest compression actually compresses the heart and large arteries of the thorax and most of the effort goes into deforming the chest and rib cage. The force needed to provide effective chest compression creates risk of other injuries. It 15 is well known that placement of the hands over the sternum is required to avoid puncture of the heart during CPR. Numerous other injuries have been caused by chest compression. See Jones and Fletter, Complications After Cardiopulmonary Resuscitation, 12 AM. J. Emerg. Med. 687 (Nov. 1994), which indicates that 20 lacerations of the heart, coronary arteries, aortic aneurysm and rupture, fractured ribs, lung herniation, stomach and liver lacerations have been caused by CPR. Thus the risk of injury attendant to chest compression is high, and clearly may reduce the chances of survival of the patient vis-à-vis a resuscitation 25 technique that could avoid those injuries. Chest compression will be completely ineffective for very large or obese cardiac arrest patients because the chest cannot be compressed enough to cause blood flow. Chest compression via pneumatic devices is hampered in its application to females due to the lack of 30 provision for protecting the breasts from injury and applying compressive force to deformation of the thoracic cavity rather than the breasts.

CPR and chest compression should be initiated as quickly as possible after cardiac arrest to maximize its effectiveness and avoid neurologic damage due to lack of blood flow to the brain. Hypoxia sets in about two minutes after cardiac arrest, and

5 brain damage is likely after about four minutes without blood flow to the brain, and the severity of neurologic defect increases rapidly with time. A delay of two or three minutes significantly lowers the chance of survival and increases the probability and severity of brain damage. However, CPR and ACLS

10 are unlikely to be provided within this time frame. Response to cardiac arrest is generally considered to occur in four phases, including action by Bystander CPR, Basic Life Support, Advanced Cardiac Life Support, and the Emergency Room. By-stander CPR occurs, if at all, within the first few minutes after cardiac

15 arrest. Basic Life Support is provided by First Responders who arrive on scene about 4-6 minutes after being dispatched to the scene. First responders include ambulance personnel, emergency medical technicians, firemen and police. They are generally capable of providing CPR but cannot provide drugs or

20 intravascular access, defibrillation or intubation. Advanced Life Support is provided by paramedics or nurse practitioners who generally follow the first responders and arrive about 8-15 minutes after dispatch. ALS is provided by paramedics, nurse practitioners or emergency medical doctors who are generally

25 capable of providing CPR, drug therapy including intravenous drug delivery, defibrillation and intubation. The ALS providers may work with a patient for twenty to thirty minutes on scene before transporting the patient to a nearby hospital. Though defibrillation and drug therapy is often successful in reviving

30 and sustaining the patient, CPR is often ineffective even when performed by well trained first responders and ACLS personnel because chest compression becomes ineffective when the providers

become fatigued. Thus, the initiation of CPR before arrival of first responders is critical to successful life support. Moreover, the assistance of a mechanical chest compression device during the Basic Life Support and Advanced Life Support 5 stages is needed to maintain the effectiveness of CPR.

Summary

The devices described below provide for circumferential chest compression with a device which is compact, portable or transportable, self-powered with a small power source, and easy 10 to use by by-standers with little or no training. Additional features may also be provided in the device to take advantage of the power source and the structural support board contemplated for a commercial embodiment of the device.

The device includes a broad belt which wraps around the 15 chest and is buckled in the front of the cardiac arrest patient. The belt is repeatedly tightened around the chest to cause the chest compression necessary for CPR. The buckle may include an interlock which must be activated by proper attachment before the device will activate, thus preventing futile belt cycles. 20 The operating mechanism for repeatedly tightening the belt is provided in a small box locatable at the patient's side, and comprises a rolling mechanism which takes up the intermediate length of the belt to cause constriction around the chest. The roller is powered by a small electric motor, and the motor 25 powered by batteries and/or standard electrical power supplies such as 120V household electrical sockets or 12V DC automobile power sockets (car cigarette lighter sockets). The belt is contained in a cartridge which is easily attached and detached from the motor box. The cartridge itself may be folded for 30 compactness. The motor is connected to the belt through a

transmission that includes a cam brake and a clutch, and is provided with a controller which operates the motor, clutch and cam brake in several modes. One such mode provides for limiting belt travel according to a high compression threshold, and

5 limiting belt travel to a low compression threshold. Another such mode includes holding the belt taught against relaxation after tightening the belt, and thereafter releasing the belt. Respiration pauses, during which no compression takes place to permit CPR respiration, can be included in the several modes.

10 Thus, numerous inventions are incorporated into the portable resuscitation device described below.

Detailed Description of the Inventions

Figure 1 shows an overview of the resuscitation device 1. 15 The major components are provided in modular form, and include the motor box 2, the belt cartridge 3 and the belt 4. The motor box exterior includes a sprocket 5 in drive wheel 6 which releasable mates with receiving rod 7 on the cartridge. The cartridge houses the belt which will wrap around the chest of 20 the patient. The cartridge also includes the spool 8 which is turned by the receiving rod. The spool takes up the midpoint of the belt to drive the compression cycles. A computer control system 10 may be included as shown in an enclosure mounted on the motor box. By providing the system in modular form, with 25 the motor box releasable attached to the belt cartridge, the belt cartridge may more easily be maneuvered while slipping it under the patient.

Figure 2 shows a more detailed view of the cartridge, including the internal mechanisms of the belt cartridge 3. The

outer body of the cartridge provides for protection of the belt during storage, and includes a back plate 11 with a left panel 11L and a right panel 11R (relative to the patient during use). The right plate can be folded over the left plate for storage

5 and transport. Both panels are covered with a sheet 12 of low friction material such as PTFE (Teflon®) to reduce friction when the belt slides over the panel during operation. Under the left panel, the cartridge has a housing 13 which houses the middle portion of the belt, the spool 8 and the spindle 15. The

10 lateral side 14 of the cartridge (corresponding to the anatomic position when in use on a patient) houses the drive spool 8, with its drive rod 7 which engages the drive wheel 6 of the motor box. The cartridge also houses the guide spindle 15 (visible in Figure 3) for directing the belt toward the drive

15 spindle 8. The guide spindle is located near the center of the cartridge (corresponding to the medial line of the patient when in use), so that it is located near the spine when the device is in use. This spindle reverses the belt travel for the left side of the belt, so that when it is pulled to the left by the drive

20 spool, the portion that wraps around the left flank of the body moves to the right. The cartridge body is also hinged near the mid-line, and in this view the cartridge is hinged near the axis of the spindle. A friction liner 16 is suspended over the belt in the area of the guide spindle, and is attached to the housing

25 at the top and bottom panels 13t and 13b and spans the area in which the left belt portions and right belt portions diverge from the cartridge. The belt 4 is shown in the open condition. Male quick release fittings 17R on the right belt portion fit into corresponding female quick release 17L fitting on the left

30 belt portion to releasably secure the belt around the patient's chest. The belt length on the left and right sides of the belt may be adjusted so that the buckles fall just over the center of

the patient's chest during operation, or they may be adjusted for placement of the buckles elsewhere around the chest. The handle 18 is provided for convenient handling and carrying of the device.

5 Figure 3 shows a cross section of the belt cartridge. The housing 13 is relatively flat, (but may be wedge shaped to assist in sliding it under a patient) when viewed from the superior position. The left panel 11L sits atop the housing 13 and the right panel extends from the housing. In the unfolded 10 position, the cartridge is flat enough to be slipped under a patient from the side. In the cross section view, the guide spindle 15 can be seen, and the manner in which the belt is threaded through the slot 9 of the drive spool 8 appears more clearly. The belt 4 comprises a single long band of tough 15 fabric threaded through the drive spool slot 9 and extending from the drive spool to the right side quick releases 17R and also from the drive spool, over and around the guide spindle, and back toward the drive spool to the left side quick releases 17L. The belt is threaded through the drive spool 8 at its mid- 20 portion, and around the guide spindle, where the left belt portion 4L folds around the guide spindle, under the friction liner and back to the left side of the cartridge, and the right belt portion 4R passes the spindle to reach around the patient's right side. The friction belt liner 16 is suspended above the 25 guide spindle and belt, being mounted on the housing, and fits between the patient and the compression belt. The cartridge is placed under the patient 20, so that the guide spindle is located close to the spine 21 and substantially parallel to the spine, and the quick release fittings may be fastened over the 30 chest in the general area of the sternum 22.

In use, the cartridge is slipped under the patient 20 and the left and right quick releases are connected. As shown in Figure 4, when the drive spool is rotated, it takes up the middle portion of the belt and tightens the belt around the 5 chest. The compression force exerted by the belt is more than sufficient to induce or increase intrathoracic pressure necessary for CPR. When the belt is spooled around the drive spool 8, the chest of the patient is compressed significantly, as illustrated.

10 While it will usually be preferred to slide the cartridge under the patient, this is not necessary. The device may be fitted onto the patient with the buckles at the back or side, or with the motor to the side or above the patient, whenever space restrictions require it. As show in Figure 5, the cartridge may 15 be fitted onto a patient 20 with only the right belt portion 4R and right panel 11R slipped under the patient, and with the right panel and left panel partially unfolded. The placement of the hinge between the right side and left side panels permits flexibility in installation of the device. Figure 6 shows that 20 the cartridge may also be fitted onto a patient 20 with both the right panel 11R and the left panel 11L slipped under the patient, but with the motor box 2 folded upward, rotated about the axis of the drive spool 8. These configurations are permitted by the modular nature of the motor box connection to 25 the belt cartridge, and will prove useful in close spaces such as ambulances and helicopters. (Note that, though the belt may be tightened by spooling operation in either direction, tightening in the direction of arrow 23, clockwise when viewed from the top of the patient and the device, will cause reactive 30 force which urges the motor box to rotate into the device, toward the body, rather than outwardly away from the body. Locking pins may be provided to prevent any rotational movement

between the motor box and the cartridge. In the construction of the motor box as shown, the limited height of the box (the height of the box is less than the distance between the left flank of the patient and the drive spool) prevents contact with 5 the patient in case the locking pins are not engaged for any reason. The rotation of the drive belt may be reversed to a counter clockwise direction, in which reactive force will urge the motor box to rotate outwardly. In this case, locking mechanisms such as locking pins can be used to protect operators 10 from movement of the system.)

Regardless of the orientation of the panels, the reversing spindle will properly orient the travel of the belt to ensure compression. The placement of the spindle at the point where the right belt portion and the left belt portion diverge under 15 the patient's chest, and the placement of this spindle in close proximity to the body, permits the belt to make contact with the chest at substantially all points on the circumference of the chest. The position of the spindle reverses the travel of the belt left portion 4L from a transverse right to left direction 20 to a transverse left to right direction, while the fact that belt right portion 4R bypasses the spindle means that it always moves from right to left in relation to the patient when pulled by the drive spool. Thus the portions of the belt engaging the chest always pull from opposite lateral areas of the chest to a 25 common point near a central point. In Figures 3 and 4, the opposite lateral areas correspond to the anatomic lateral area of the patient, and the central point corresponds to the spine. In Figure 5, the lateral areas correspond to the spine and anterior left side of the torso, while the central point 30 corresponds to the left lateral area of the chest.

Additionally, the use of the single spindle at the center of the body, with the drive spool placed at the side of the body,

permits simple construction and the detachable or modular embodiment of the motor assembly, and allows placement of the belt about the patient before attachment of the motor box to the entire device.

5 Figure 7 illustrates an embodiment of the compression belt which reduces the take up speed for a given motor speed or gearing and allows for twice the compressive force for a given motor speed. The compression belt comprises a loop **24** of belt material. The loop is threaded through the complex path around
10 spindles **25** in the quick release fasteners **26**, around the body to the guide spindle **15**, around or past the guide spindle and into the drive spool **8**. The left belt portion outer layer **27L** and right belt portion outer layer **27R** form, together with the left belt portion inner layer **28L** and right belt portion inner
15 layer **28R** form a continuos loop running inwardly from the fastener spindle, inwardly around the chest to the opposite drive spindle, outwardly from the opposite drive spindle, downwardly over the chest, past the guide spindle to the drive spool, through the drive spool slot and back under the guide
20 spindle, reversing around the guide spindle and upwardly over the chest back to the fastener spindle. Thus both the inner and outer layers of this two layer belt are pulled toward the drive spool to exert compressive force on the body. This can provide for a decrease in friction as the belts will act on each other
25 rather than directly on the patient. It will also allow for a lower torque, higher speed motor to exert the necessary force.

 In Figure 8, the double layer belt system is modified with structure which locks the inner belt portion in place, and prevents it from moving along the body surface. This has the
30 advantage that the major portion of the belt in contact with the body does not slide relative to the body. To lock the belt

inner layer in place relative to the loop pathway, the locking bar 29 is fixed within the housing 13 in parallel with the guide spindle 15 and the drive spool 8. The inner loop may be secured and fastened to the locking bar, or it may be slidably 5 looped over the locking bar (and the locking bar may be rotatable, as a spindle). The left belt portion outer layer 27L and right belt portion outer layer 27R are threaded through the drive spool 8. With the locking bar installed, the rotation of the drive spool takes up the outer layer of the belt, and these 10 outer layers are forced to slide over the left belt portion inner layer 28L and right belt portion inner layer 28R, but the inner layers do not slide relative to the surface of the patient (except, possibly, during a brief few cycles in which the belt centers itself around the patient, which will occur 15 spontaneously due to the forces applied to the belt.)

In Figure 9, the double layer belt system is modified with structure which does not lock the inner belt portion in place or prevent it from moving along the body surface, but instead provides a second drive spool to act on the inner layer of the 20 belt. To drive the belt inner layer relative to the loop pathway, the secondary drive spool 30 is fixed within the housing 13 in parallel with the guide spindle 15 and the drive spool 8. This secondary drive spool is driven by the motor, either through transmission geared within the housing or through 25 a second receiving rod protruding from the housing and a secondary drive socket driven through appropriate gearing in the motor box. The inner loop may be secured and fastened to the secondary drive spool, or it may be threaded through the secondary drive spool slot 31. The left belt portion outer 30 layer 27L and right belt portion outer layer 27R are threaded through the first drive spool 8. With the secondary drive spool, the rotation of the first drive spool 8 takes up the outer layer

of the belt, and these outer layers are forced to slide over the left belt portion inner layer **28L** and right belt portion inner layer **28R**, while the secondary drive spool takes up the inner layers.

5 The compression belt may be provided in several forms. It is preferably made of some tough material such as parachute cloth or tyvek. In the most basic form shown in Figure 10, the belt **4** is a plain band of material with fastening ends **32L** and **32R**, corresponding left and right belt portions **4L** and **4R**, and
10 the spool engaging center portion **33**. While we have used the spool slot in combination with the belt being threaded through the spool slot as a convenient mechanism to engage the belt in the drive spool, the belt may be fixed to the drive spool in any manner. In Figure 11, the compression belt is provided in two
15 distinct pieces comprising left and right belt portions **4L** and **4R** connected with a cable **34** which is threaded through the drive spool. This construction permits a much shorter drive spool, and may eliminate friction within the housing inherent in the full width compression band of Figure 10. The fastening
20 ends **32L** and **32R** are fitted with hook and loop fastening elements **35** which may be used as an alternative to other quick release mechanisms. To provide a measurement of belt pay-out and take-up during operation, the belt or cable may be modified with the addition of a linear encoder scale, such as scale **36** on
25 the belt near the spool engaging center portion **33**. A corresponding scanner or reader may be installed on the motor box, or in the cartridge in apposition to the encoder scale.

Figure 12 illustrates the configuration of the motor and clutch within the motor box. The exterior of the motor box
30 includes a housing **41**, and a computer module **10** with a convenient display screen **42** for display of any parameters

measured by the system. The motor 43 is a typical small battery operated motor which can exert the required belt tensioning torque. The motor shaft 44 is lined up directly to the brake 45 which includes reducing gears and a cam brake to control free spinning of the motor when the motor is not energized (or when a reverse load is applied to the gearbox output shaft). The gearbox output rotor 46 connects to a wheel 47 and chain 48 which connect to the input wheel 49, and thereby to the transmission rotor 50 of the clutch 51. The clutch 51 controls whether the input wheel 49 engages the output wheel 52, and whether rotary input to the input wheel is transmitted to the output wheel. (The secondary brake 53, which we refer to as the spindle brake, provides for control of the system in some embodiments, as explained below in reference to Figure 17.) The output wheel 52 is connected to the drive spool 8 via the chain 54 and drive wheel 6 and receiving rod 7 (the drive rod is on the cartridge). The drive wheel 6 has receiving socket 5 which is sized and shaped to mate and engage with the drive rod 7 (simple hexagonal or octagonal sprocket which matches the drive rod is sufficient). While we use a wrap spring brake (a MAC 45 sold by Warner Electric) for the cam brake in the system, any form of brake may be employed. The wrap spring brake has the advantage of allowing free rotating of the shaft when de-energized, and holds only when energized. The wrap spring brake may be operated independent of the motor. While we use chains to transmit power through the system, belts, gears or other mechanisms may be employed.

Figure 12a illustrates the configuration of the motor and clutch within the motor box. The exterior of the motor box includes a housing 41 which holds the motor 43 is a typical small battery operated motor which can exert the required belt tensioning torque. The motor shaft 44 is lined up directly to

the brake 45 which includes reducing gears and a cam. The gearbox output rotor 46 connects to brake to the output wheel 47 and chain 48 which in turn connects directly to the drive wheel 6 and receiving rod 7. The drive spool 8 is contained within 5 the housing 41. At the end of the drive spool opposite the drive wheel, the brake 55 is directly connected to the drive spool. The belt 4 is threaded through the drive spool slot 9. To protect the belt from rubbing on the motor box, the shield 57 with the long aperture 58 is fastened to the housing so that the 10 aperture lies over the drive spool, allowing the belt to pass through the aperture and into the drive spool slot, and return out of the housing. Under the housing, slidably disposed within a channel in the bottom of the housing, a push plate 70 is positioned so that it can slide back and forth relative to the 15 housing. The belt right portion 4 is fitted with a pocket 71 which catches or mates with the right tip 72 of the push plate. The right tip of the push plate is sized and dimensioned to fit within the pocket. By means of this mating mechanism, the belt can be slipped onto the push plate, and with the handle 73 on 20 the left end of the push plate, the push plate together with the right belt portion can be pushed under a patient. The belt includes the encoder scale 36, which can be read with an encoder scanner mounted on or within the housing. In use, the belt right portion is slipped under the patient by fastening it to 25 the push plate and sliding the push plate under the patient. The motor box can then be positioned as desired around the patient (the belt will slip through the drive spool slot to allow adjustment). The belt right side can then be connected to the belt left portion so that the fastened belt surrounds the 30 patient's chest. In both Figures 12 and 12a, the motor is mounted in side-by-side relationship with the clutch and with the drive spool. With the side-by-side arrangement of the motor

and the roller, the motor may be located to the side of the patient, and need not be placed under the patient, or in interfering position with the shoulders or hips. This also allows a more compact storage arrangement of the device, vis-à-vis an in-line connection between the motor and the roller. A battery is placed within the box or attached to the box as space allows.

During operation, the action of the drive spool and belt draw the device toward the chest, until the shield is in contact with the chest (with the moving belt interposed between the shield and the chest). The shield also serves to protect the patient from any rough movement of the motor box, and help keep a minimum distance between the rotating drive spool and the patient's skin, to avoid pinching the patient or the patient's clothing in the belt as the two sides of the belt are drawn into the housing. As illustrated in Figure 12b, the shield 57 may also include two lengthwise apertures 74 separated by a short distance. With this embodiment of the shield, one side of the belt passes through one aperture and into the drive spool slot, and the other side of the belt exits from the drive spool slot and outwardly through the other aperture in the shield. The shield as shown has an arcuate transverse cross section (relative to the body on which it is installed). This arcuate shape permits the motor box to lay on the floor during use while a sufficient width of shield extends between the box and the belt. The shield made of plastic, polyethylene, PTFE, or other tough material which allows the belt to slide easily. The motor box, may, however, be placed anywhere around the chest of the patient.

A computer module which acts as the system controller is placed within the box or attached to the box and is operably

connected to the motor, the cam brake, clutch, encoder and other operating parts, as well as biological and physical parameter sensors included in the overall system (blood pressure, blood oxygen, end tidal CO₂, body weight, chest circumference, etc.

5 are parameters that can be measured by the system and incorporated into the control system for adjusting compression rates and torque thresholds, or belt pay-out and slack limits). The computer module can also be programmed to handle various ancillary tasks such as display and remote communications,
10 sensor monitoring and feedback monitoring, as illustrated in our prior application 08/922,723.

The computer is programmed (with software or firmware or otherwise) and operated to repeatedly turn the motor and release the clutch to roll the compression belt onto the drive spool
15 (thereby compressing the chest of the patient) and release the drive spool to allow the belt to unroll (thereby allowing the belt and the chest of the patient to expand), and hold the drive spool in a locked or braked condition during periods of each cycle. The computer is programmed to monitor input from various
20 sensors, such as the torque sensor or belt encoders, and adjust operation of the system in response to these sensed parameters by, for example, halting a compression stroke or slipping the clutch (or brake) in response to torque limit or belt travel limits. As indicated below, the operation of the motor box
25 components may be coordinated to provide for a squeeze and hold compression method which prolongs periods of high intrathoracic pressure. The system may be operated in a squeeze and quick release method for more rapid compression cycles and better waveform and flow characteristics in certain situations. The
30 operation of the motor box components may be coordinated to provide for a limited relaxation and compression, to avoid wasting time and battery power to move the belt past compression

threshold limits or slack limits. The computer is preferably programmed to monitor two or more sensed parameters to determine an upper threshold for belt compression. By monitoring motor torque as measured by a torque sensor and paid out belt length as determined by a belt encoder, the system can limit the belt take-up with redundant limiting parameters. The redundancy provided by applying two limiting parameters to the system avoids over-compression in the case that a single compression parameter exceed the safe threshold while the system fails to sense and respond the threshold by stopping belt take-up.

An angular optical encoder may be placed on any rotating part of the system to provide feedback to a motor controller relating to the condition of the compression belt. (The encoder system may be an optical scale coupled to an optical scanner, a magnetic or inductive scale coupled to a magnetic or inductive encoder, a rotating potentiometer, or any one of the several encoder systems available.) The encoder 56, for example, is mounted on the secondary brake 53 (in Figure 12), and provides an indication of the motor shaft motion to a system controller. An encoder may also be placed on the drive socket 5 or drive wheel 6, the motor 43 and or motor shaft 44. The system includes a torque sensor (sensing current supply to the motor, for example), and monitors the torque or load on the motor. For either or both parameters, a threshold is established above which further compression is not desired or useful, and if this occurs during the compression of the chest, then the clutch is disengaged. The belt encoder is used by the control system to track the take-up of the belt, and to limit the length of belt which is spooled upon the drive belt.

In order to control the amount of thoracic compression (change in circumference) for the cardiac compression device

using the encoder, the control system must establish a baseline or zero point for belt take-up. When the belt is tight to the point where any slack has been taken up, the motor will require more current to continue to turn under the load of compressing 5 the chest. This expected rapid increase in motor current draw (motor threshold current draw) is measured through torque sensor (an Amp meter, a voltage divider circuit or the like). This spike in current or voltage is taken as the signal that the belt has been drawn tightly upon the patient and the paid out belt 10 length is an appropriate starting point, and the encoder measurement at this point is zeroed within the system (that is, taken as the starting point for belt take-up). The encoder then provides information used by the system to determine the change in length of the belt from this pre-tightened position. 15 The ability to monitor and control the change in length allows the controller to control the amount of pressure exerted on the patient and the change in volume of the patient by limiting the length of belt take-up during a compression cycle.

The expected length of belt take-up for optimum compression 20 is 1 to 6 inches. However, six inches of travel on a thin individual may create a excessive change in thoracic circumference and present the risk of injury from the device. In order to overcome this problem, the system determines the necessary change in belt length required by measuring the amount 25 of belt travel required to become taught as described above. Knowing the initial length of the belt and subtracting off the amount required to become taught will provide a measure of the patient's size (chest circumference). The system then relies on predetermined limits or thresholds to the allowable change in 30 circumference for each patient on which it is installed, which can be used to limit the change in volume and pressure applied to the patient. The threshold may change with the initial

circumference of the patient so that a smaller patient will receive less of a change in circumference as compared to a larger patient. The encoder provides constant feedback as to the state of travel and thus the circumference of the patient at 5 any given time. When the belt take-up reaches the threshold (change in volume), the system controller ends the compression stroke and continues into the next period of hold or release as required by the compression/ decompression regimen programmed into the controller. The encoder also enables the system to 10 limit the release of the belt so that it does not fully release. This release point can be determined by the zero point established on the pre-tightening first take-up, or by taking a percentage of the initial circumference or a sliding scale triggered by the initial circumference of the patient.

15 The belt could also be buckled so that it remains tight against the patient. Requiring the operator to tighten the belt provides for a method to determine the initial circumference of the patient. Again encoders can determine the amount of belt travel and thus can be used to monitor and limit the amount of 20 change in the circumference of the patient given the initial circumference.

Several compression and release patterns may be employed to boost the effectiveness of the CPR compression. Typical CPR compression is accomplished at 60-80 cycles per minute, with the 25 cycles constituting mere compression followed by complete release of compressive force. This is the case for manual CPR as well as for known mechanical and pneumatic chest compression devices. With our new system, compression cycles in the range of 20-70 cpm have been effective, and the system may be operated 30 as high as 120 cpm or more. This type of compression cycle can be accomplished with the motor box with motor and clutch

operation as indicated in Figure 13. When the system is operating in accordance with the timing table of Figure 13, the motor is always on, and the clutch cycles between engagement (on) and release (off). After several compressions at time 5 periods T1, T3, T5 and T7, the system pauses for several time periods to allow brief period (several seconds) to provide a respiration pause, during which operators may provide ventilation or artificial respiration to the patient, or otherwise cause oxygenated air to flow into the patient's lungs. 10 (The brakes illustrated in Figure 12, are not used in this embodiment, though they may be installed.) The length of the clutch engagement period is controlled in the range of 0-2000 msec, and the time between periods of clutch engagement is controlled in the range of 0-2000 msec (which of course is 15 dictated by medical considerations and may change as more is learned about the optimal rate of compression).

The timing chart of Figure 13a illustrates the intra-thoracic pressure changes caused by the compression belt when operated according to the timing diagram of Figure 13. The 20 chest compression is indicated by the status line 59. The motor is always on, as indicated by motor status line 60. The clutch is engaged or "on" according to the square wave clutch status line 61 in the lower portion of the diagram. Each time the clutch engages, the belt is tightened around the patient's 25 chest, resulting in a high pressure spike in belt tension and intra-thoracic pressure as indicated by the compression status line 62. Pulses p1, p2, p3, p4 and p5 are all similar in amplitude and duration, with the exception of pulse p3. Pulse p3 is limited in duration in this example to show how the torque 30 limit feedback operates to prevent excessive belt compression. (Torque limit may be replaced by belt travel or other parameter as the limiting parameter.) As an example of system response to

sensing the torque limit, Pulse p3 is shown rapidly reaching the torque limit set on the motor. When the torque limit is reached, the clutch disengages to prevent injury to the patient and excessive drain on the battery (excessive compression is 5 unlikely to lead to additional blood flow, but will certainly drain the batteries quickly). Note that after clutch disengagement under pulse p3, belt tension and intra-thoracic pressure drop quickly, and the intra-thoracic pressure is increased for only a small portion of cycle. After clutch 10 disengagement based on an over-torque condition, the system returns to the pattern of repeated compressions. Pulse P4 occurs at the next scheduled compression period T7, after which the respiration pause period spanning T8, T9, and T10 is created by maintaining the clutch in the disengaged condition. After 15 the respiration pause, pulse P5 represents the start of the next set of compressions. The system repeatedly performs sets of compressions followed by respiration pauses until interrupted by the operator.

Figure 14 illustrates the timing of the motor, clutch and 20 cam brake in a system that allows the belt compression to be reversed by reversing the motor. It also provides for compression hold periods to enhance the hemodynamic effect of the compression periods, and relaxation holds to limit the belt pay-out in the relaxation period to the point where the belt is 25 still taut on the chest and not excessively loose. As the diagram indicates, the motor operates first in the forward direction to tighten the compression belt, then is turned off for a brief period, then operates in the reverse direction and turns off, and continues to operate through cycles of forward, 30 off, reverse, off, and so on. In parallel with these cycles of the motor state, the cam brake is operating to lock the motor drive shaft in place, thereby locking the drive roller in place

and preventing movement of the compression belt. Brake status line 63 indicates the status of the brake 45. Thus, when the motor tightens the compression belt up to the threshold or time limit, the motor turns off and the cam brake engages to prevent the compression belt from loosening. This effectively prevents relaxation of the patient's chest, maintaining a higher intra-thoracic pressure during hold periods T2, T6 and T10. Before the next compression cycle begins, the motor is reversed and the cam brake is disengaged, allowing the system to drive the belt to a looser length and allowing the patient's chest to relax. Upon relaxation to the lower threshold corresponding to the pre-tightened belt length, the cam brake is energized to stop the spindle and hold the belt at the pre-tightened length. The clutch is engaged at all times (the clutch may be omitted altogether if no other compression regimen is desired in the system). (This embodiment may incorporate two motors operating in different directions, connecting to the spindle through clutches.)

Figure 14a illustrates the intra-thoracic pressure changes caused by the compression belt when operated according to the timing diagram of Figure 14a. The clutch, if any, is always on as indicated by clutch status line 61. The cam brake is engaged or "on" according to the square wave in the lower portion of the diagram. The motor is on, off, or reversed according to motor state line. Each time the motor is turned on in the forward direction, the belt is tightened around the patient's chest, resulting in a high pressure spike in belt tension and intra-thoracic pressure as shown in the pressure plot line. Each time the high threshold limit is sensed by the system and the motor is de-energized, the cam brake engages to prevent further belt movement. This results in a high maintained pressure or "hold pressure" during the hold periods indicated on the diagram (time

period T2, for example). At the end of the hold period, the motor is reversed to drive the belt to a relaxed position, then de-energized. When the motor is turned off after a period of reverse operation, the cam brake engages to prevent excess slackening of the compression belt (this would waste time and battery power). The cam brake disengages when the cycle is reinitiated and the motor is energized to start another compression. Pulses p1, p2, are similar in amplitude and duration. Pulse p3 is limited in duration in this example to show how the torque limit feedback operates to prevent excessive belt compression. Pulse p3 rapidly reaches the torque limit set on the motor (or the take-up limit set on the belt), and the motor stops and the cam brake engages to prevent injury to the patient and excessive drain on the battery. Note that after motor stop and cam brake engagement under pulse p3, belt tension and intra-thoracic pressure are maintained for the same period as all other pulses, and the intra-thoracic pressure is decreased only slightly, if at all, during the high pressure hold period. After pulse, P3, a respiration pause may be initiated in which the belt tension is permitted to go completely slack.

Figure 15 illustrates the timing of the motor, clutch and cam brake in a system that allows the belt compression to completely relax during each cycle. As the table indicates, the motor operates only in the forward direction to tighten the compression belt, then is turned off for a brief period, and continues to operate through on and off cycles. In the first time period T1, the motor is on and the clutch is engaged, tightening the compression belt about the patient. In the next time period t2, the motor is turned off and the cam brake is energized (with the clutch still engaged) to lock the compression belt in the tightened position. In the next time

period T3, the clutch is disengaged to allow the belt to relax and expand with the natural relaxation of the patient's chest. In the next period t4, the motor is energized to come up to speed, while the clutch is disengaged and the cam brake is off.

5 The motor comes up to speed with no effect on the compression belt in this time period. In the next time period, the cycle repeats itself. Thus, when the motor tightens the compression belt up to the threshold or time limit, the motor turns off and the cam brake engages to prevent the compression belt from

10 loosening. This effectively prevents relaxation of the patient's chest, maintaining a higher intra-thoracic pressure. Before the next compression cycle begins, the clutch is disengaged, allowing the chest to relax and allowing the motor to come up to speed before coming under load. This provides

15 much more rapid belt compression, leading to a sharper increase in intra-thoracic pressure.

Figure 15a illustrates the intra-thoracic pressure changes caused by the compression belt when operated according to the timing table of Figure 15. The clutch is turned on only after

20 the motor has come up to speed, according to the clutch status line 61 and motor status line 60, which shows that the motor is energized for two time periods before clutch engagement. The cam brake is engaged or "on" according to the brake status line 62 in the lower portion of the diagram. Each time the clutch is

25 engaged, the belt is tightened around the patient's chest, resulting in a sharply increasing high pressure spike in belt tension and intra-thoracic pressure as shown in the pressure plot line. Each time the motor is de-energized, the cam brake engages and clutch remains engaged to prevent further belt

30 movement, and the clutch prevents relaxation. This results in a high maintained pressure or "hold pressure" during the hold periods indicated on the diagram. At the end of the hold

period, the clutch is de-energized to allow the belt to expand to the relaxed position. At the end of the cycle, the cam brake is disengaged (with the clutch disengaged) to allow the motor to come up to speed before initiation of the next compression cycle. The next cycle is initiated when the clutch is engaged. This action produces the sharper pressure increase at the beginning of each cycle, as indicated by the steep curve at the start of each of the pressure Pulses p1, p2, and p3. Again, these pressure pulses are all similar in amplitude and duration, with the exception of pulse p2. Pulse p2 is limited in duration in this example to show how the torque limit feedback operates to prevent excessive belt compression. Pulse p2 rapidly reaches the torque limit set on the motor, and the motor stops and the cam brake engages to prevent injury to the patient and excessive drain on the battery. Note that after motor stop and cam brake engagement under pulse p2, belt tension and intra-thoracic pressure are maintained for the same period as all other pulses, and the intra-thoracic pressure is decreased only slightly during the hold period. The operation of the system according to Figure 15a is controlled to limit belt pressure to a threshold measured by high motor torque (or, correspondingly, belt strain or belt length).

Figure 16 illustrates the timing of the motor, clutch and cam brake in a system that does not allow the belt compression to completely relax during each cycle. Instead, the system limits belt relaxation to a low threshold of motor torque, belt strain, or belt length. As the table indicates, the motor operates only in the forward direction to tighten the compression belt, then is turned off for a brief period, and continues to operate through on and off cycles. In the first time period T1, the motor is on and the clutch is engaged, tightening the compression belt about the patient. In the next

time period t2, the motor is turned off and the cam brake is energized (with the clutch still engaged) to lock the compression belt in the tightened position. In the next time period T3, the clutch is disengaged to allow the belt to relax 5 and expand with the natural relaxation of the patient's chest. The drive spool will rotate to pay out the length of belt necessary to accommodate relaxation of the patient's chest. In the next period t4, while the motor is still off, the clutch is engaged (with the cam brake still on) to prevent the belt from 10 becoming completely slack. To start the next cycle at T5, the motor starts and the cam brake is turned off and another compression cycle begins.

Figure 16a illustrates the intrathoracic pressure and belt strain that corresponds to the operation of the system according 15 to Figure 16. Motor status line 60 and the brake status line 62 indicate that when the motor tightens the compression belt up to the high torque threshold or time limit, the motor turns off and the cam brake engages to prevent the compression belt from loosening. Thus the high pressure attained during uptake of the 20 belt is maintained during the hold period starting at T2. When the belt is loosened at T3 by release of the clutch (which uncouples the cam brake), the intrathoracic pressure drops as indicated by the pressure line. At T4, after the compression belt has loosened to some degree, but not become totally slack, 25 the clutch engages (and recouples the cam brake) to hold the belt at some minimum level of belt pressure. This effectively prevents total relaxation of the patient's chest, maintaining a slightly elevated intra-thoracic pressure even between compression cycles. A period of low level compression is 30 created within the cycle. Note that after several cycles (four or five cycles) a respiration pause is incorporated into the compression pattern, during which the clutch is off, the cam

brake is off to allow for complete relaxation of the belt and the patient's chest. (The system may be operated with the low threshold in effect, and no upper threshold in effect, creating a single low threshold system.) The motor may be energized 5 between compression period, as shown in time periods T11 and T12, to bring it up to speed before the start of the next compression cycle.

Figure 17 shows a timing table for use in combination with a system that uses the motor, clutch, and secondary brake 53 or 10 a brake on drive wheel or the spindle itself. The brake 45 is not used in this embodiment of the system (though it may be installed in the motor box). As the table indicates, the motor operates only in the forward direction to tighten the compression belt, and is always on. In the first time period 15 T1, the motor is on and the clutch is engaged, tightening the compression belt about the patient. In the next time period t2, the motor is on but the clutch is disengaged and the brake 53 is energized to lock the compression belt in the tightened position. In the next time period T3, the clutch is disengaged 20 and the brake is off to allow the belt to relax and expand with the natural relaxation of the patient's chest. The drive spool will rotate to pay out the length of belt necessary to accommodate relaxation of the patient's chest. In the next period t4, while the motor is still on, the clutch is 25 disengaged, but energizing the spindle brake is effective to lock the belt prevent the belt from becoming completely slack (in contrast to the systems described above, the operation of the spindle brake is effective when the clutch is disengaged because the spindle brake is downstream of the clutch). To 30 start the next cycle at T5, the motor starts and the spindle brake is turned off, the clutch is engaged and another compression cycle begins. During pulse P3, the clutch is

engaged for time periods T11 and T12 while the torque threshold limit is not achieved the system. This provides an overshoot compression period, which can be interposed amongst the torque limited compression periods.

5 Figure 17a illustrates the intrathoracic pressure and belt strain that corresponds to the operation of the system according to Figure 17. Motor status line 60 and the brake status line 62 indicate that when the motor tightens the compression belt up to the high torque threshold or time limit, the spindle brake
10 engages (according to spindle brake status line 64) and the clutch disengages to prevent the compression belt from loosening. Thus the high pressure attained during uptake of the belt is maintained during the hold period starting at T2. When the belt is loosened at T3 by release of the spindle brake, the
15 intrathoracic pressure drops as indicated by the pressure line. At T4, after the compression belt has loosened to some degree, but not become totally slack, the spindle brake engages to hold the belt at some minimum level of belt pressure. This effectively prevents total relaxation of the patient's chest,
20 maintaining a slightly elevated intra-thoracic pressure even between compression cycles. A period of low level compression is created within the cycle. At P3, the upper threshold is not achieved but the maximum time allowed for compression is reached, so and the clutch is engaged for two time periods T9
25 and T10 until the system releases the clutch based on the time limit. At T9 and T10, the spindle brake, though enabled, is not turned on.

Figure 18 shows a timing table for use in combination with a system that uses the motor, clutch, and secondary brake 53 or
30 a brake on drive wheel or the spindle itself. The brake 45 is not used in this embodiment of the system (though it may be

installed in the motor box). As the table indicates, the motor operates only in the forward direction to tighten the compression belt, and is always on. In the time periods T1 and T2, the motor is on and the clutch is engaged, tightening the compression belt about the patient. In contrast to the timing chart of Figure 17, the brake is not energized to hold the belt during the compression periods (T1 and T2) unless the upper threshold is achieved by the system. In the next time period T3, the clutch is disengaged and the brake is off to allow the belt to relax and expand with the natural relaxation of the patient's chest. The drive spool will rotate to pay out the length of belt necessary to accommodate relaxation of the patient's chest. During T3, the belt pays out to the zero point, so the system energizes the spindle brake. During T4, the motor remains on, the clutch is disengaged, and the spindle brake is effective to lock the belt to prevent the belt from becoming completely slack (in contrast to the systems using the cam brake, the operation of the spindle brake is effective when the clutch is disengaged because the spindle brake is downstream of the clutch). To start the next cycle at T5, the motor starts and the spindle brake is turned off, the clutch is engaged and another compression cycle begins. The system achieves the high threshold during time period T6, at peak P2, and causes the clutch to release and the spindle brake to engage, thereby holding the belt tight in the high compression state for the remainder of the compression period (T5 and T6). At the end of the compression period, the brake is momentarily disengaged to allow the belt to expand to the low threshold or zero point, and the brake is engaged again to hold the belt at the low threshold point. Pulse P3 is created with another compression period in which brake is released and the clutch is engaged in T9 and T10, until the threshold is reached, whereupon the clutch disengages

and the brake engages to finish the compression period with the belt held in the high compression state. In time period T11 and T12, the clutch is disengaged and the brake is release to allow the chest to relax completely. This provides for a respiration 5 pause in which the patient may be ventilated.

Figure 18a illustrates the intrathoracic pressure and belt strain that corresponds to the operation of the system according to Figure 18. In time periods T1 and T2, the motor status line 60 and the brake status line 62 indicate that the motor tightens 10 the compression belt up the end of the compression period (the system will not initiate a hold below the upper threshold). When the belt is loosened at T3 by release of the spindle brake, the intrathoracic pressure drops as indicated by the pressure line. At T3, after the compression belt has loosened to some degree, 15 but not become totally slack, the spindle brake engages to hold the belt at some minimum level of belt pressure. This effectively prevents total relaxation of the patient's chest, maintaining a slightly elevated intra-thoracic pressure even between compression cycles. A period of low level compression 20 is created within the cycle. Motor status line 60 and the brake status line 62 indicate that when the motor tightens the compression belt up to the high torque threshold or time limit, the spindle brake engages (according to spindle brake status line 64) and the clutch disengages to prevent the compression 25 belt from loosening. Thus the high pressure attained during uptake of the belt is maintained during the hold period starting at T6. When the belt is loosened at T7 by release of the spindle brake, the intrathoracic pressure drops as indicated by the pressure line. At T7, after the compression belt has 30 loosened to some degree, but not become totally slack, the spindle brake engages to hold the belt at the lower threshold. At P3, the upper threshold is again achieved, so and the clutch

is disengaged and the brake is engaged at time T10 to initiate the high compression hold.

Figure 19 shows a timing table for use in combination with a system that uses the motor, clutch, and secondary brake 53 or 5 a brake on drive wheel or the spindle itself. The brake 45 is not used in this embodiment of the system (though it may be installed in the motor box). As the table indicates, the motor operates only in the forward direction to tighten the compression belt, and is always on. In the first time period 10 T1, the motor is on and the clutch is engaged, tightening the compression belt about the patient. In the next time period t2, the motor is on, the clutch is disengaged in response to the sensed threshold, and the brake 53 is enabled and energized to lock the compression belt in the tightened position only if the 15 upper threshold is sensed during the compression period. In the next time period T3, the clutch is disengaged and the brake is off to allow the belt to relax and expand with the natural relaxation of the patient's chest. The drive spool will rotate to pay out the length of belt necessary to accommodate 20 relaxation of the patient's chest. In the next period t4, while the motor is still on, the clutch is disengage, but energizing the spindle brake is effective to lock the belt prevent the belt from becoming completely slack (in contrast to the systems described above, the operation of the spindle brake is effective 25 when the clutch is disengaged because the spindle brake is downstream of the clutch). To start the next cycle at T5, the motor starts and the spindle brake is turned off, the clutch is engaged and another compression cycle begins. During pulse P3, the clutch is on in time period T9. The clutch remains engaged 30 and the brake is enabled but not energized in time period T10. The clutch and brake are controlled in response to the threshold, meaning that the system controller is awaiting until

the high threshold is sensed before switching the system to the hold configuration in which the clutch is released and the brake is energized. In this example, the high threshold is not achieved during the compression period T9 and T10, so the system

5 does not initiate a hold.

Figure 19a illustrates the intrathoracic pressure and belt strain that corresponds to the operation of the system according to Figure 19. Motor status line 60 and the brake status line 62 indicate that when the motor tightens the compression belt up to

10 the high torque threshold or time limit, where the clutch disengages and the spindle brake engages (according to spindle brake status line 64) to prevent the compression belt from loosening. Thus the high pressure attained during uptake of the belt is maintained during the hold period starting at T2. Thus

15 the period of compression comprises a period of active compressing of the chest followed by a period of static compression. When the belt is loosened at T3 by release of the spindle brake, the intrathoracic pressure drops as indicated by the pressure line. At T4, after the compression belt has

20 loosened to some degree, but not become totally slack, the spindle brake engages to hold the belt at some minimum level of belt pressure. This effectively prevents total relaxation of the patient's chest, maintaining a slightly elevated intra-thoracic pressure even between compression cycles. A period of

25 low level compression is created within the cycle. Note that in cycles where the upper threshold is not achieved, the compression period does not include a static compression (hold) period, and the clutch is engaged for two time periods T9 and T10, and the system eventually ends the active compression based

30 on the time limit set by the system.

Figure 20 shows a timing table for use in combination with a system that uses the motor, clutch, the cam brake within gearbox 45 and secondary brake 53 or a brake on drive wheel or the spindle itself. Both brakes are used in this embodiment of the system. As the table indicates, the motor operates only in the forward direction to tighten the compression belt. In the first time period T1, the motor is on and the clutch is engaged, tightening the compression belt about the patient. In the next time period t2, the upper threshold is achieved and the motor is turned off in response to the sensed threshold, the clutch is still engaged, and the secondary brake 53 is enabled and energized to lock the compression belt in the tightened position (these events happens only if the upper threshold is sensed during the compression period). In the next time period T3, with the clutch disengaged and the brakes off, the belt relaxes and expands with the natural relaxation of the patient's chest. The drive spool will rotate to pay out the length of belt necessary to accommodate relaxation of the patient's chest. In the next period t4 (while the motor is still on), the clutch remains disengaged, but energizing the secondary brake is effective to lock the belt to prevent the belt from becoming completely slacks. To start the next cycle at T5, the spindle brake is turned off, the clutch is engaged and another compression cycle begins (the motor has been energized earlier, in time period T3 or T4, to bring it up to speed). During pulse P3, the clutch is on in time period T9. The clutch remains engaged and the brake is enabled but not energized in time period T10. The clutch and brake are controlled in response to the threshold, meaning that the system controller is awaiting until the high threshold is sensed before switching the system to the hold configuration in which the clutch is released and the brake is energized. In this example, the high threshold is

not achieved during the compression period T9 and T10, so the system does not initiate a hold. The cam brake serves to hold the belt in the upper threshold length, and the spindle brake serves to hold the belt in the lower threshold length.

5 Figure 20a illustrates the intrathoracic pressure and belt strain that corresponds to the operation of the system according to Figure 20. Motor status line 60 and the brake status line 62 indicate that when the motor tightens the compression belt up to the high torque threshold or time limit, the motor turns off and
10 the cam brake engages (according to cam brake status line 63) to prevent the compression belt from loosening (the clutch remains engaged). Thus the high pressure attained during uptake of the belt is maintained during the hold period starting at T2. Thus the period of compression comprises a period of active
15 compressing of the chest followed by a period of static compression. When the belt is loosened at T3 by release of the clutch, the intrathoracic pressure drops as indicated by the pressure line. At T4, after the compression belt has loosened to some degree, but not become totally slack, the spindle brake
20 engages to hold the belt at some minimum level of belt pressure, as indicated by the spindle brake status line 64. This effectively prevents total relaxation of the patient's chest, maintaining a slightly elevated intra-thoracic pressure even between compression cycles. A period of low level compression
25 is created within the cycle. Note that in cycles where the upper threshold is not achieved, the compression period does not include a static compression (hold) period, and the clutch is engaged for two time periods T9 and T10, and the system eventually ends the active compression based on the time limit
30 set by the system.

The previous figures have illustrated control systems in a time dominant system, even where thresholds are used to limit the active compression stroke. We expect the time dominant system will be preferred to ensure a consistent number of 5 compression periods per minute, as is currently preferred in the ACLS. Time dominance also eliminates the chance of a runaway system, where the might be awaiting indication that a torque or encoder threshold has been met, yet for some reason the system does not approach the threshold. However, it may be 10 advantageous in some systems, perhaps with patients closely attended by medical personnel, to allow the thresholds to dominate partially or completely. An example of partial threshold dominance is indicated in the table of Figure 21. The compression period is not timed, and ends only when the upper 15 threshold is sensed at point a. The system operates the clutch and brake to allow relaxation to the lower threshold at point b, and then initiates the low threshold hold period. At a set time after the peak compression, a new compression stroke is initiated at point c, and maintained until the peak compression 20 is reached at point d. The actual time spent in the active compression varies depending on how long it takes the system to achieve the threshold. Thus cycle time (a complete period of active compression, release and low threshold hold, until the start of the next compression) varies with each cycle depending 25 on how long it takes the system to achieve the threshold, and the low threshold relaxation period floats accordingly. To avoid extended periods in which the system stalls while awaiting an upper threshold that is never achieved, outer time limit is imposed on each compression period, as illustrated at point g, 30 where the compression is ended before reaching the maximum allowed compression. In essence, the system clock is reset each time the upper threshold is achieved. The preset time limits 75

for low compression hold periods are shifted leftward on the diagram of Figure 21a, to floating time limits 76. This approach can be combined with each of the previous control regimens by resetting the timing whenever those systems reach 5 the upper threshold.

The arrangement of the motor, cam brake and clutch may be applied to other systems for belt driven chest compressions. For example, Lach, Resuscitation Method And Apparatus, U.S. Patent 4,770,164 (Sep. 13, 1988) proposes a hand-cranked belt 10 that fits over the chest and two chocks under the patient's chest. The chocks hold the chest in place while the belt is cranked tight. Torque and belt tightness are limited by a mechanical stop which interferes with the rotation of the large drive roller. The mechanical stop merely limits the tightening 15 roll of the spool, and cannot interfere with the unwinding of the spool. A motor is proposed for attachment to the drive rod, and the mate between the motor shaft and the drive roller is a manually operated mechanical interlock referred to as a clutch. This "clutch" is a primitive clutch that must be set by hand 20 before use and cannot be operated during compression cycles. It cannot release the drive roller during a cycle, and it cannot be engaged while the motor is running, or while the device is in operation. Thus application of the brake and clutch arrangements described above to a device such as Lach will be 25 necessary to allow that system to be automated, and to accomplish the squeeze and hold compression pattern.

Lach, Chest Compression Apparatus for Cardiac Arrest, PCT App. PCT/US96/18882 (Jun. 26. 1997) also proposes a compression belt operated by a scissor-like lever system, and proposes 30 driving that system with a motor which reciprocatingly drives the scissor mechanism back and forth to tighten and loosen the

belt. Specifically, Lach teaches that failure of full release is detrimental and suggests that one cycle of compression would not start until full release has occurred. This system can also be improved by the application of the clutch and brake systems
5 described above. It appears that these and other belt tensioning means can be improved upon by the brake and clutch system. Lach discloses a number of reciprocating actuators for driving the belt, and requires application of force to these actuators. For example, the scissor mechanism is operated by
10 applying downward force on the handles of the scissor mechanism, and this downward force is converted into belt tightening force by the actuator. By motorizing this operation, the advantages of our clutch and brake system can be obtained with each of the force converters disclosed in Lach. The socketed connection
15 between the motor and drive spool can be replaced with a flexible drive shaft connected to any force converter disclosed in Lach.

Thus, while the preferred embodiments of the devices and methods have been described in reference to the environment in
20 which they were developed, they are merely illustrative of the principles of the inventions. Other embodiments and configurations may be devised without departing from the spirit of the inventions and the scope of the appended claims.
